# CS 188x: Artificial Intelligence

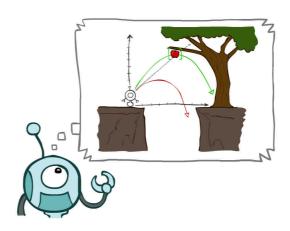

## Search

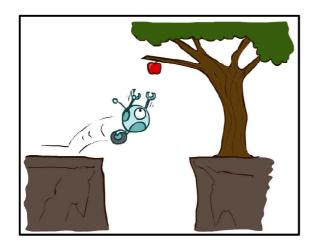

Dan Klein, Pieter Abbeel University of California, Berkeley

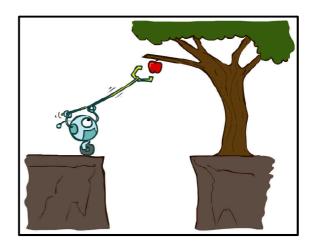

# Today

- Agents that Plan Ahead
- Search Problems
- Uninformed Search Methods
  - Depth-First Search
  - Breadth-First Search
  - Uniform-Cost Search

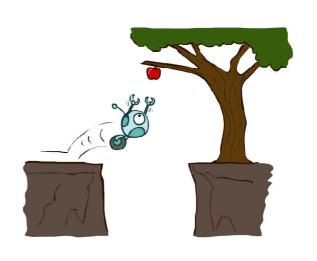

# Agents that Plan

# **Reflex Agents**

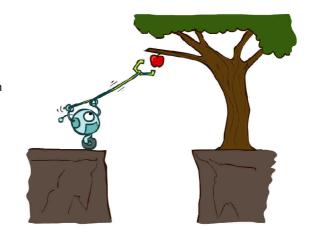

- Reflex agents:
  - Choose action based on current percept (and maybe memory)
  - May have memory or a model of the world's current state
  - Do not consider the future consequences of their actions
  - Consider how the world IS
- Can a reflex agent be rational?

[demo: reflex optimal / loop ]

## **Planning Agents**

- Planning agents:
  - Ask "what if"
  - Decisions based on (hypothesized) consequences of actions
  - Must have a model of how the world evolves in response to actions
  - Must formulate a goal (test)
  - Consider how the world WOULD BE
- Optimal vs. complete planning
- Planning vs. replanning

[demo: plan fast / slow ]

## Search Problems

- A search problem consists of:
  - A state space

 A successor function (with actions, costs)

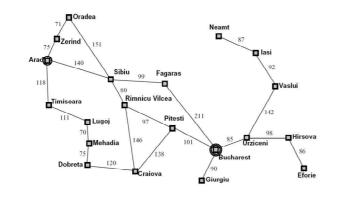

- A start state and a goal test
- A solution is a sequence of actions (a plan) which transforms the start state to a goal state

## Search Problems Are Models

# Example: Traveling in Romania

- State space:
  - Cities
- Successor function:
  - Roads: Go to adjacent city with cost = distance
- Start state:
  - Arad
- Goal test:
  - Is state == Bucharest?
- Solution?

## What's in a State Space?

The world state includes every last detail of the environment

A search state keeps only the details needed for planning (abstraction)

- Problem: Pathing
  - States: (x,y) location
  - Actions: NSEW
  - Successor: update location only
  - Goal test: is (x,y)=END

- Problem: Eat-All-Dots
  - States: {(x,y), dot booleans}
  - Actions: NSEW
  - Successor: update location and possibly a dot boolean
  - Goal test: dots all false

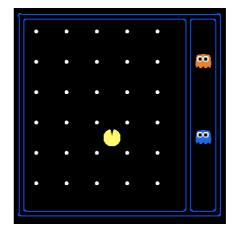

## State Space Sizes?

## World state:

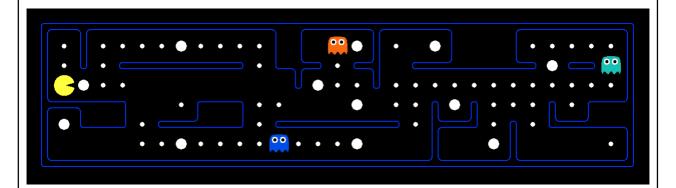

- Agent positions: 120
- Food count: 30
- Ghost positions: 12
- Agent facing: NSEW

## How many

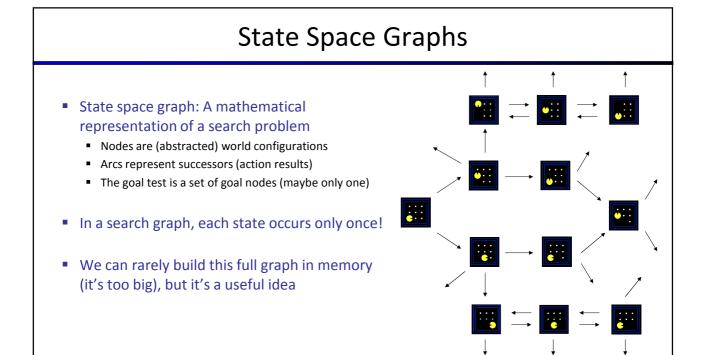

- World states?
   120x(2<sup>30</sup>)x(12<sup>2</sup>)x4
- States for pathing?120
- States for eat-all-dots? 120x(2<sup>30</sup>)

## Quiz: Safe Passage

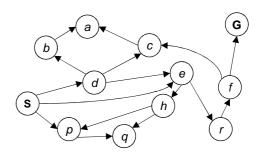

- Problem: eat all dots while keeping the ghosts perma-scared
- What does the state space have to specify?
  - (agent position, dot booleans, power pellet booleans, remaining scared time)

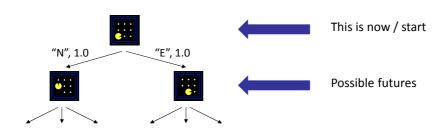

## **State Space Graphs**

- State space graph: A mathematical representation of a search problem
  - Nodes are (abstracted) world configurations
  - Arcs represent successors (action results)
  - The goal test is a set of goal nodes (maybe only one)
- In a search graph, each state occurs only once!
- We can rarely build this full graph in memory (it's too big), but it's a useful idea

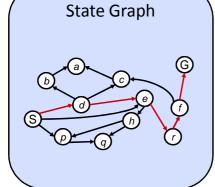

Tiny search graph for a tiny search problem

## **Search Trees**

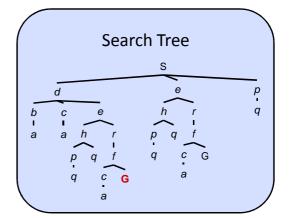

- A search tree:
  - A "what if" tree of plans and their outcomes
  - The start state is the root node
  - Children correspond to successors
  - Nodes show states, but correspond to PLANS that achieve those states
  - For most problems, we can never actually build the whole tree

# State Graphs vs. Search Trees

Each NODE in in the search tree is an entire PATH in the problem graph.

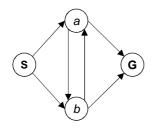

We construct both on demand – and we construct as little as possible.

## Quiz: State Graphs vs. Search Trees

Consider this 4-state graph:

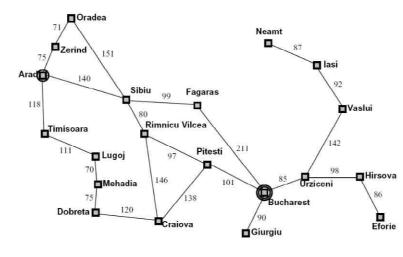

How big is its search tree (from S)?

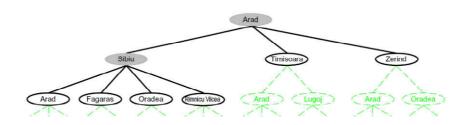

Important: Lots of repeated structure in the search tree!

# Searching with a Search Tree

## Search:

- Expand out potential plans (tree nodes)
- Maintain a fringe of partial plans under consideration
- Try to expand as few tree nodes as possible

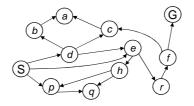

## **General Tree Search**

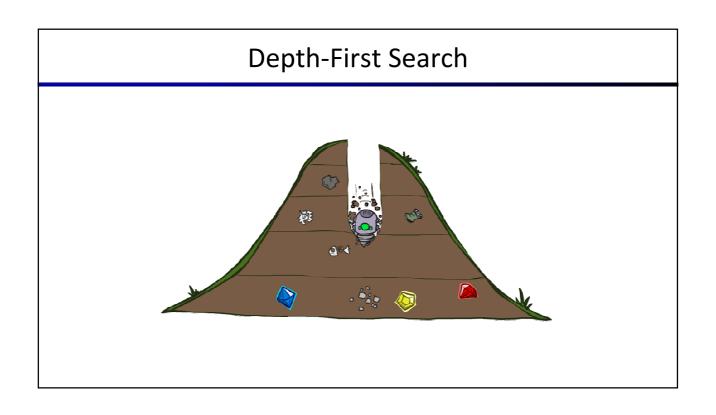

function TREE-SEARCH (problem, strategy) returns a solution, or failure initialize the search tree using the initial state of problem loop do

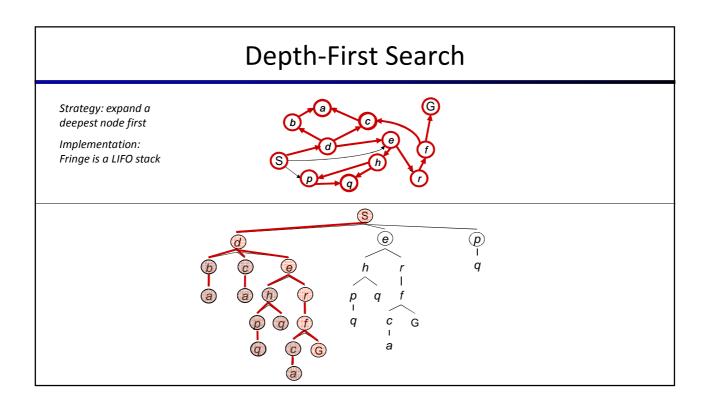

if there are no candidates for expansion then return failure choose a leaf node for expansion according to strategy if the node contains a goal state then return the corresponding solution else expand the node and add the resulting nodes to the search tree add

- Important ideas:
  - Fringe
  - Expansion
  - Exploration strategy
- Main question: which fringe nodes to explore?

# Example: Tree Search

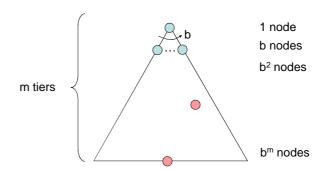

## Search Algorithm Properties

- Complete: Guaranteed to find a solution if one exists?
- Optimal: Guaranteed to find the least cost path?
- Time complexity?
- Space complexity?
- Cartoon of search tree:
  - b is the branching factor
  - m is the maximum depth
  - solutions at various depths

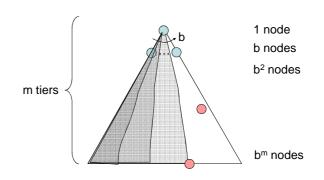

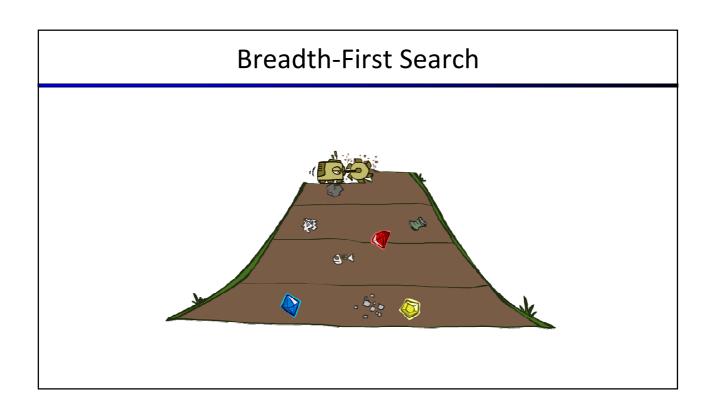

■  $1 + b + b^2 + .... b^m = O(b^m)$ 

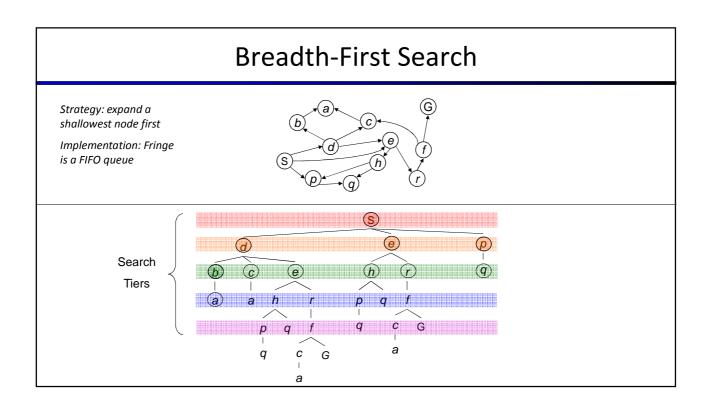

## Depth-First Search (DFS) Properties

- What nodes DFS expand?
  - Some left prefix of the tree.
  - Could process the whole tree!
  - If m is finite, takes time O(b<sup>m</sup>)
- How much space does the fringe take?
  - Only has siblings on path to root, so O(bm)
- Is it complete?
  - m could be infinite, so only if we prevent cycles (more later)
- Is it optimal?
  - No, it finds the "leftmost" solution, regardless of depth or cost

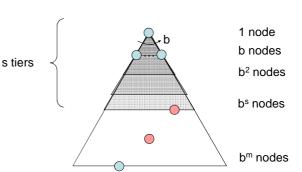

## Breadth-First Search (BFS) Properties

- What nodes does BFS expand?
  - Processes all nodes above shallowest solution
  - Let depth of shallowest solution be s
  - Search takes time O(b<sup>s</sup>)
- How much space does the fringe take?
  - Has roughly the last tier, so O(bs)
- Is it complete?
  - s must be finite if a solution exists, so yes!
- Is it optimal?
  - Only if costs are all 1 (more on costs later)

## Quiz: DFS vs BFS

- When will BFS outperform DFS?
- When will DFS outperform BFS?

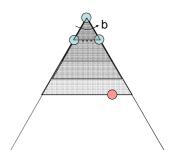

[demo: dfs/bfs]

## **Iterative Deepening**

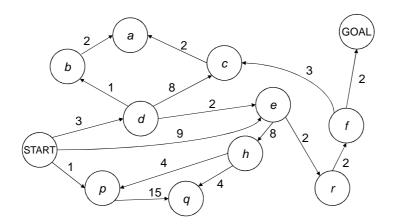

- Idea: get DFS's space advantage with BFS's time / shallow-solution advantages
  - Run a DFS with depth limit 1. If no solution...
  - Run a DFS with depth limit 2. If no solution...
  - Run a DFS with depth limit 3. .....

Generally most work happens in the lowest level searched, so not so bad!

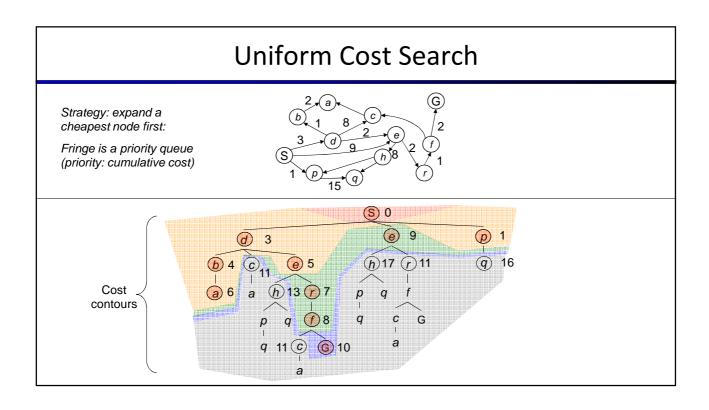

## **Cost-Sensitive Search**

BFS finds the shortest path in terms of number of actions. It does not find the least-cost path. We will now cover a similar algorithm which does find the least-cost path.

## **Uniform Cost Search (UCS) Properties**

 $C*/\varepsilon$  "tiers"

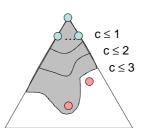

- What nodes does UFS expand?
  - Processes all nodes with cost less than cheapest solution!
  - If that solution costs  $C^*$  and arcs cost at least  $\varepsilon$ , then the "effective depth" is roughly  $C^*/\varepsilon$
  - Takes time  $O(b^{C*/\epsilon})$  (exponential in effective depth)

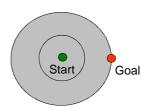

- Has roughly the last tier, so  $O(b^{C^*/\varepsilon})$
- Is it complete?
  - Assuming best solution has a finite cost and minimum arc cost is positive, yes!
- Is it optimal?
  - Yes! (Proof next lecture via A\*)

## **Uniform Cost Issues**

- Remember: UCS explores increasing cost contours
- The good: UCS is complete and optimal!
- The bad:
  - Explores options in every "direction"
  - No information about goal location
- We'll fix that soon!

[demo: search demo empty]

c ≤ 1

 $c \le 2$ 

c ≤ 3

## The One Queue: Priority Queues

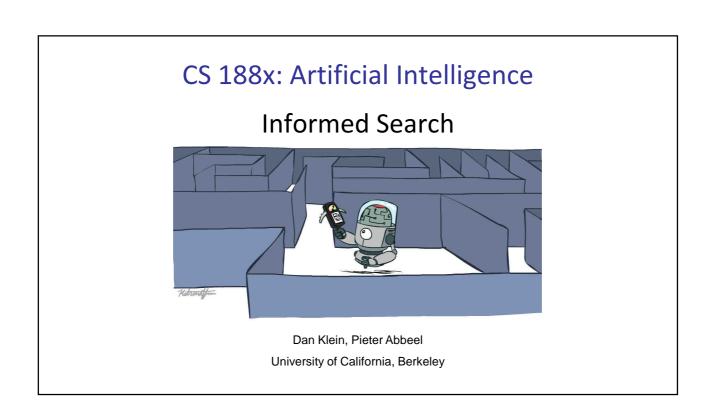

- All these search algorithms are the same except for fringe strategies
  - Conceptually, all fringes are priority queues (i.e. collections of nodes with attached priorities)
  - Practically, for DFS and BFS, you can avoid the log(n) overhead from an actual priority queue with stacks and queues
  - Can even code one implementation that takes a variable queuing object

## Search and Models

- Search operates over models of the world
  - The agent doesn't actually try all the plans out in the real world!
  - Planning is all "in simulation"
  - Your search is only as good as your models...

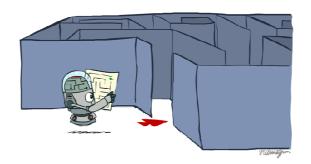

# Today

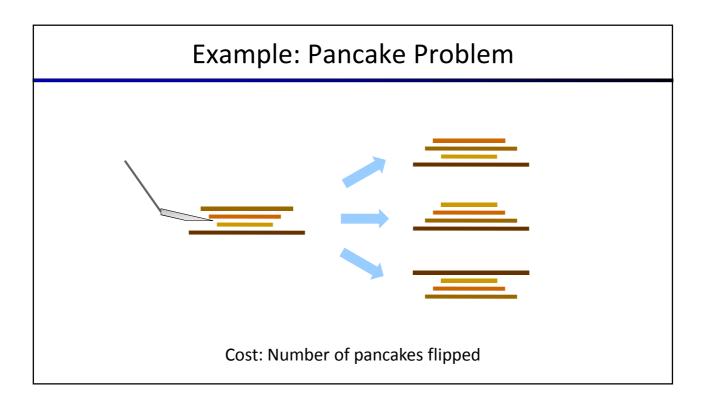

- Informed Search
  - Heuristics
  - Greedy Search
  - A\* Search
- Graph Search

## Recap: Search

- Search problem:
  - States (configurations of the world)
  - Actions and costs
  - Successor function (world dynamics)
  - Start state and goal test
- Search tree:
  - Nodes: represent plans for reaching states
  - Plans have costs (sum of action costs)
- Search algorithm:
  - Systematically builds a search tree
  - Chooses an ordering of the fringe (unexplored nodes)
  - Optimal: finds least-cost plans

## Example: Pancake Problem

## BOUNDS FOR SORTING BY PREFIX REVERSAL

William H. GATES

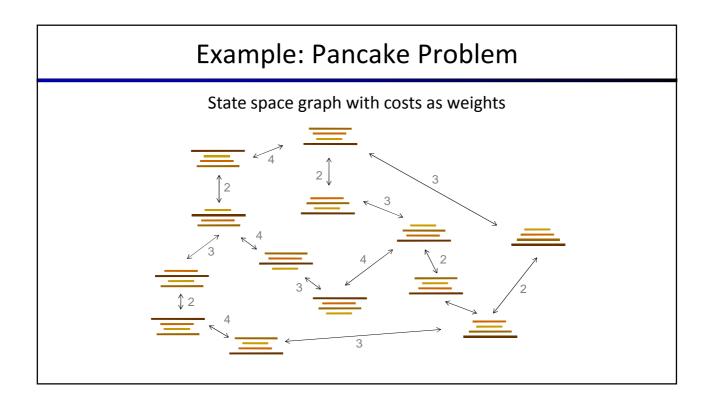

Microsoft, Albuquerque, New Mexico

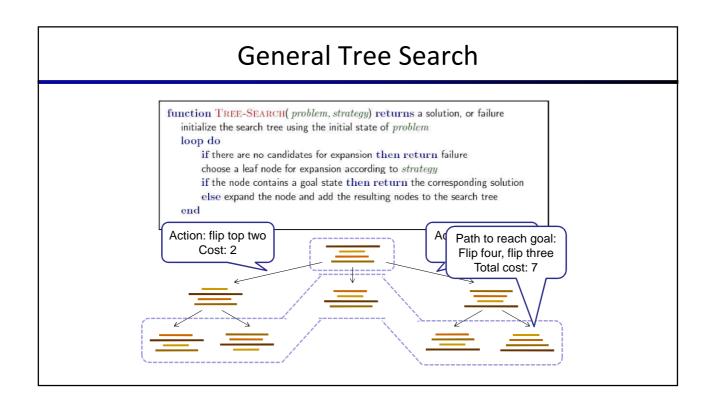

Christos H. PAPADIMITRIOU\*†

Department of Electrical Engineering, University of California, Berkeley, CA 94720, U.S.A.

Received 18 January 1978 Revised 28 August 1978

For a permutation  $\sigma$  of the integers from 1 to n, let  $f(\sigma)$  be the smallest number of prefix reversals that will transform  $\sigma$  to the identity permutation, and let f(n) be the largest such  $f(\sigma)$  for all  $\sigma$  in (the symmetric group)  $S_n$ . We show that  $f(n) \leq (5n+5)/3$ , and that  $f(n) \geq 17n/16$  for n a multiple of 16. If, furthermore, each integer is required to participate in an even number of reversed prefixes, the corresponding function g(n) is shown to obey  $3n/2-1 \leq g(n) \leq 2n+3$ .

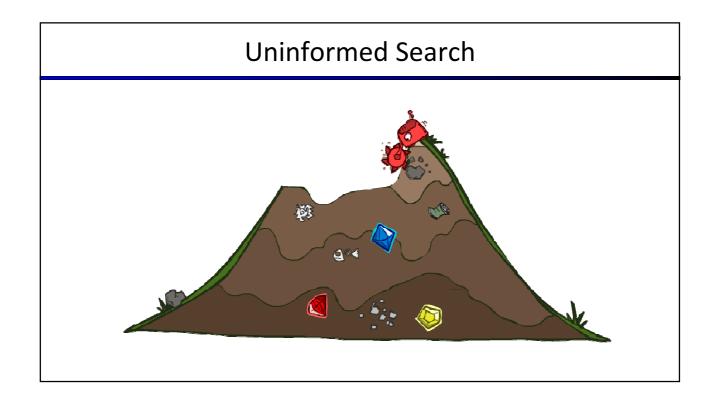

## The One Queue

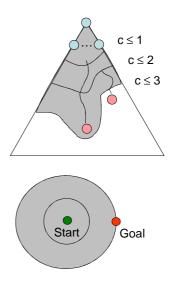

- All these search algorithms are the same except for fringe strategies
  - Conceptually, all fringes are priority queues (i.e. collections of nodes with attached priorities)
  - Practically, for DFS and BFS, you can avoid the log(n) overhead from an actual priority queue, by using stacks and queues
  - Can even code one implementation that takes a variable queuing object

## **Uniform Cost Search**

- Strategy: expand lowest path cost
- The good: UCS is complete and optimal!
- The bad:
  - Explores options in every "direction"
  - No information about goal location

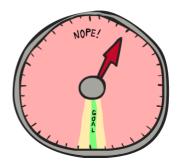

[demo: contours UCS]

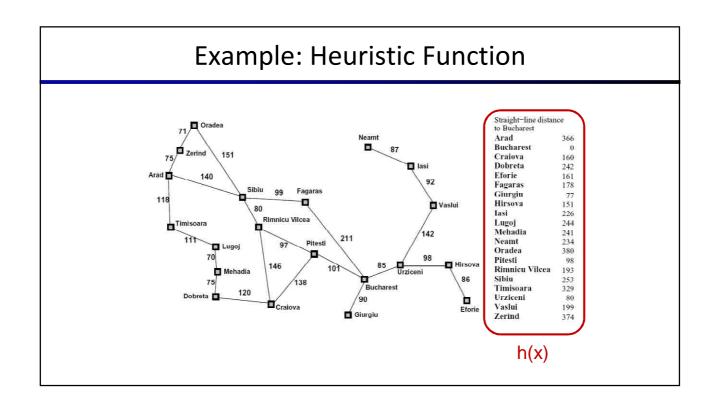

## **Informed Search**

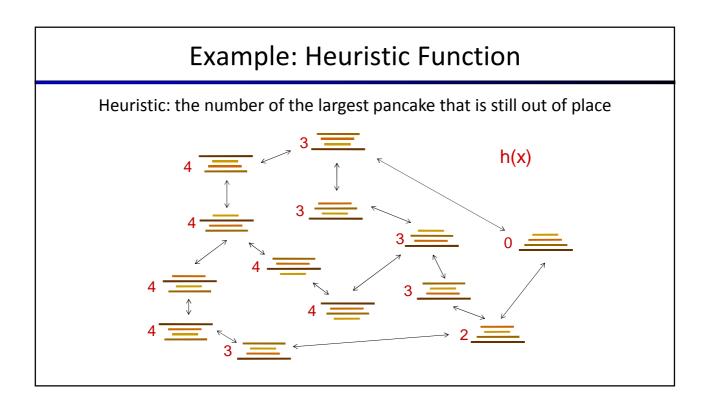

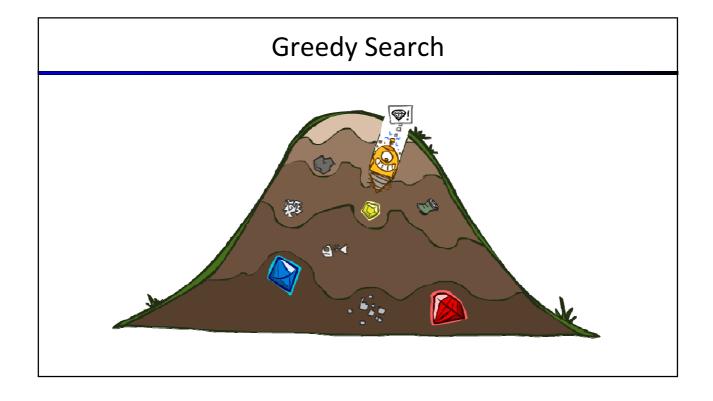

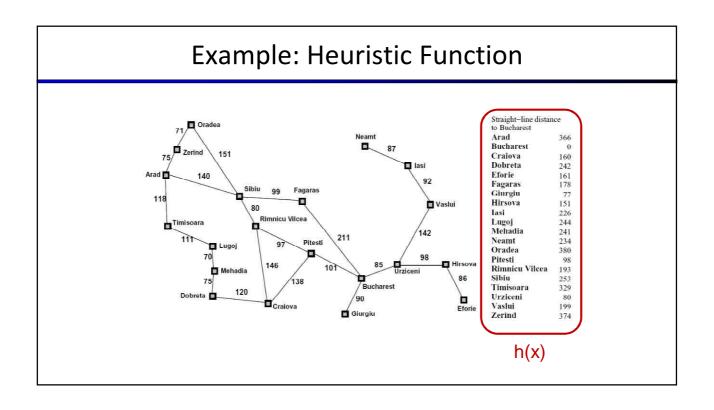

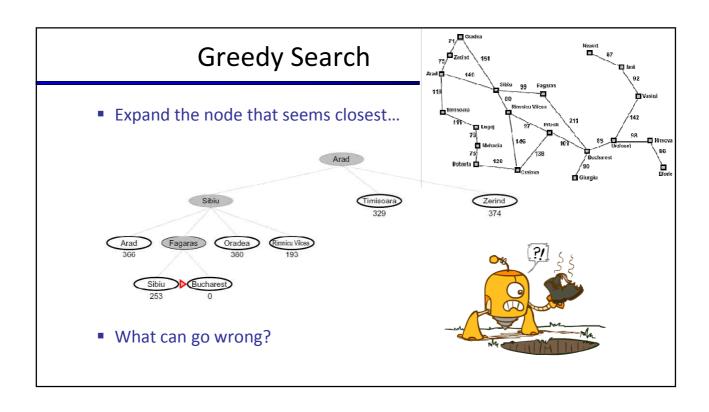

# Search Heuristics A heuristic is: A function that estimates how close a state is to a goal Designed for a particular search problem Examples: Manhattan distance, Euclidean distance for pathing

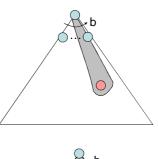

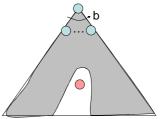

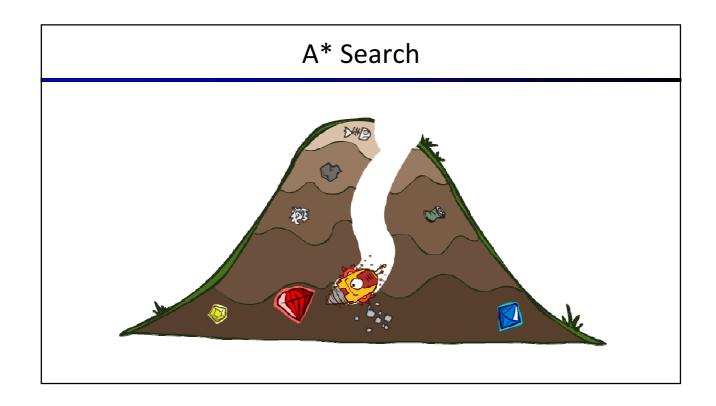

# **Greedy Search**

- Strategy: expand a node that you think is closest to a goal state
  - Heuristic: estimate of distance to nearest goal for each state
- A common case:
  - Best-first takes you straight to the (wrong) goal
- Worst-case: like a badly-guided DFS

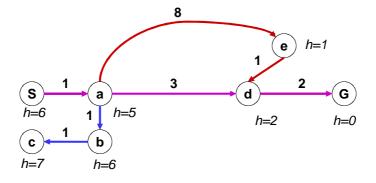

[demo: contours greedy]

## **Combining UCS and Greedy**

- Uniform-cost orders by path cost, or backward cost g(n)
- Greedy orders by goal proximity, or forward cost h(n)

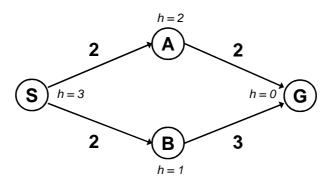

A\* Search orders by the sum: f(n) = g(n) + h(n)

Example: Teg Grenager

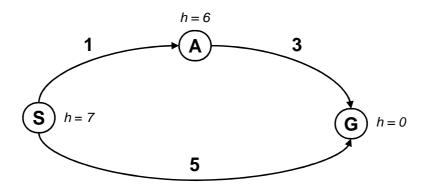

## When should A\* terminate?

Should we stop when we enqueue a goal?

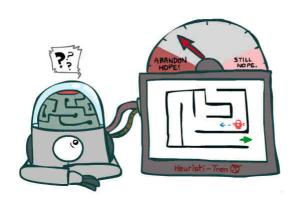

No: only stop when we dequeue a goal

## Is A\* Optimal?

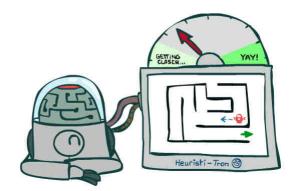

- What went wrong?
- Actual bad goal cost < estimated good goal cost</li>
- We need estimates to be less than actual costs!

# Idea: Admissibility

Inadmissible (pessimistic) heuristics break optimality by trapping good plans on the fringe

Admissible (optimistic) heuristics slow down bad plans but never outweigh true costs

## Admissible Heuristics

• A heuristic *h* is *admissible* (optimistic) if:

$$0 \le h(n) \le h^*(n)$$

where  $h^*(n)$  is the true cost to a nearest goal

• Examples:

 Coming up with admissible heuristics is most of what's involved in using A\* in practice.

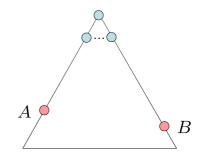

## Optimality of A\* Tree Search

### Assume:

- A is an optimal goal node
- B is a suboptimal goal node
- h is admissible

## Claim:

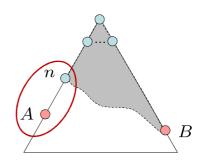

A will exit the fringe before B

## Optimality of A\* Tree Search: Blocking

## Proof:

- Imagine B is on the fringe
- Some ancestor n of A is on the fringe, too (maybe A!)
- Claim: n will be expanded before B
  - 1. f(n) is less or equal to f(A)

$$f(n) = g(n) + h(n)$$
  
$$f(n) \le g(A)$$

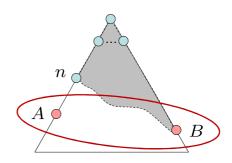

$$g(A) = f(A)$$

Definition of f-cost Admissibility of h h = 0 at a goal

## Optimality of A\* Tree Search: Blocking

## Proof:

- Imagine B is on the fringe
- Some ancestor n of A is on the fringe, too (maybe A!)
- Claim: *n* will be expanded before B
  - 1. f(n) is less or equal to f(A)
  - 2. f(A) is less than f(B) -

$$g(A) < g(B)$$

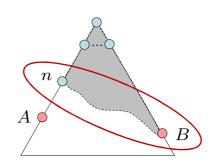

B is suboptimal h = 0 at a goal

$$f(A) < f(B)$$

# Optimality of A\* Tree Search: Blocking

## Proof:

- Imagine B is on the fringe
- Some ancestor n of A is on the fringe, too (maybe A!)
- Claim: *n* will be expanded before B
  - 1. f(n) is less or equal to f(A)
  - 2. f(A) is less than f(B)
  - 3. *n* expands before B —
- All ancestors of A expand before B
- A expands before B
- A\* search is optimal

 $f(n) \le f(A) < f(B)$ 

# Uniform-Cost A\*

## UCS vs A\* Contours

Uniform-cost expands equally in all "directions"

 A\* expands mainly toward the goal, but does hedge its bets to ensure optimality

[demo: contours UCS / A\*]

## **A\*** Applications

- Pathing / routing problems
- Video games
- Resource planning problems
- Robot motion planning
- Language analysis
- Machine translation
- Speech recognition
- ...

[demo: plan tiny UCS / A\*]

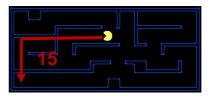

# **Creating Admissible Heuristics**

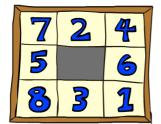

- Most of the work in solving hard search problems optimally is in coming up with admissible heuristics
- Often, admissible heuristics are solutions to relaxed problems, where new actions are available

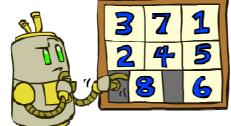

Inadmissible heuristics are often useful too

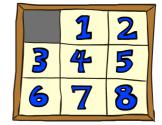

## Example: 8 Puzzle

Start State

Actions

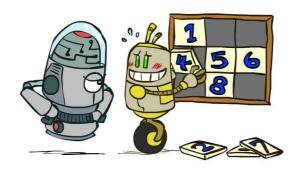

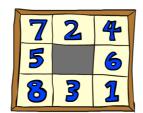

**Goal State** 

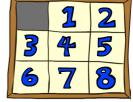

- What are the states?
- How many states?
- What are the actions?
- How many successors from the start state?
- What should the costs be?

## 8 Puzzle I

- Heuristic: Number of tiles misplaced
- Why is it admissible?
- h(start) = 8
- This is a *relaxed-problem* heuristic

Start State

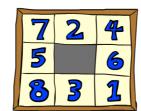

**Goal State** 

	Average nodes expanded when the optimal path has					
	4 steps	8 steps	12 steps			
UCS	112	6,300	3.6 x 10 <sup>6</sup>			
TILES	13	39	227			

Statistics from Andrew Moore

## 8 Puzzle II

What if we had an easier 8-puzzle where any tile could slide any direction at any time, ignoring other tiles?

**Goal State** 

■ Total *Manhattan* distance

Start State

Why is it admissible?

Average nodes expanded

<ul><li>h</li></ul>	(start	) =	3 +	1+	2 +	=	18
---------------------	--------	-----	-----	----	-----	---	----

	when the optimal path has				
	4 steps	8 steps	12 steps		
TILES	13	39	227		
MANHATTAN	12	25	73		

## 8 Puzzle III

- How about using the actual cost as a heuristic?
  - Would it be admissible?
  - Would we save on nodes expanded?
  - What's wrong with it?

- With A\*: a trade-off between quality of estimate and work per node
  - As heuristics get closer to the true cost, you will expand fewer nodes but usually do more work per node to compute the heuristic itself

## Trivial Heuristics, Dominance

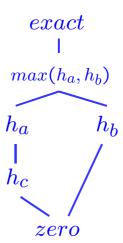

■ Dominance:  $h_a \ge h_c$  if

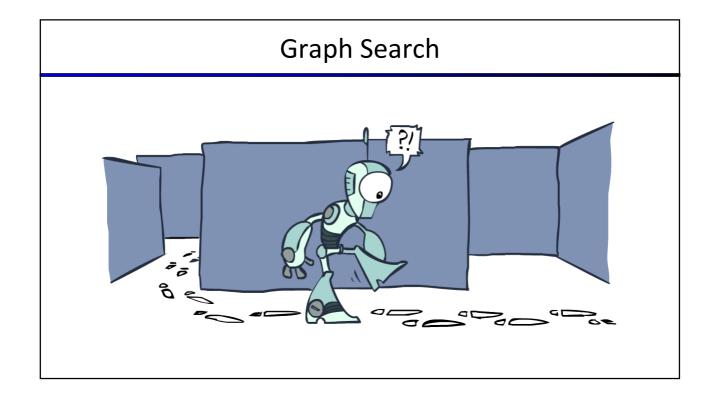

$$\forall n: h_a(n) \geq h_c(n)$$

- Heuristics form a semi-lattice:
  - Max of admissible heuristics is admissible

$$h(n) = max(h_a(n), h_b(n))$$

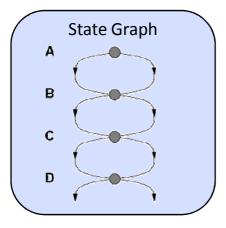

- Trivial heuristics
  - Bottom of lattice is the zero heuristic (what does this give us?)
  - Top of lattice is the exact heuristic

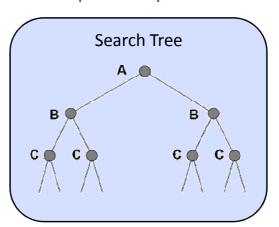

## Tree Search: Extra Work!

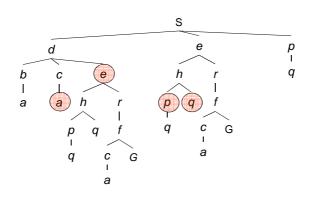

• Failure to detect repeated states can cause exponentially more work.

# **Graph Search**

■ In BFS, for example, we shouldn't bother expanding the circled nodes (why?)

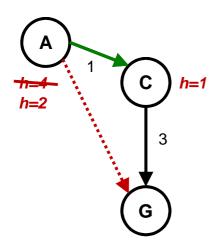

## **Graph Search**

- Idea: never expand a state twice
- How to implement:
  - Tree search + set of expanded states ("closed set")
  - Expand the search tree node-by-node, but...
  - Before expanding a node, check to make sure its state has never been expanded before
  - If not new, skip it, if new add to closed set
- Important: store the closed set as a set, not a list
- Can graph search wreck completeness? Why/why not?
- How about optimality?

# 

## **Consistency of Heuristics**

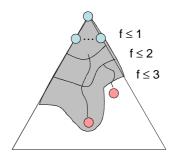

- Main idea: estimated heuristic costs ≤ actual costs
  - Admissibility: heuristic cost ≤ actual cost to goal
     h(A) ≤ actual cost from A to G
  - Consistency: heuristic cost ≤ actual cost for each arc
     h(A) h(C) ≤ cost(A to C)
- Consequences of consistency:
  - The f value along a path never decreases

 $h(A) \le cost(A to C) + h(C)$ 

A\* graph search is optimal

## Optimality of A\* Graph Search

- Sketch: consider what A\* does with a consistent heuristic:
  - Fact 1: In tree search, A\* expands nodes in increasing total f value (f-contours)
  - Fact 2: For every state s, nodes that reach s optimally are expanded before nodes that reach s suboptimally
  - Result: A\* graph search is optimal

## **Optimality**

- Tree search:
  - A\* is optimal if heuristic is admissible
  - UCS is a special case (h = 0)
- Graph search:
  - A\* optimal if heuristic is consistent
  - UCS optimal (h = 0 is consistent)
- Consistency implies admissibility
- In general, most natural admissible heuristics tend to be consistent, especially if from relaxed problems

## A\*: Summary

- A\* uses both backward costs and (estimates of) forward costs
- A\* is optimal with admissible / consistent heuristics
- Heuristic design is key: often use relaxed problems
